ABSTRACT

The European Society of Gynaecological Oncology (ESGO), the International Society of Ultrasound in Obstetrics and Gynecology (ISUOG), the International Ovarian Tumour Analysis (IOTA) group, and the European Society for Gynaecological Endoscopy (ESGE) jointly developed clinically relevant and evidence-based statements on the pre-operative diagnosis of ovarian tumors, including imaging techniques, biomarkers, and prediction models. ESGO/ISUOG/IOTA/ESGE nominated a multidisciplinary international group, including expert practising clinicians and researchers who have demonstrated leadership and expertise in the pre-operative diagnosis of ovarian tumors and management of patients with ovarian cancer (19 experts across Europe). A patient representative was also included in the group. To ensure that the statements were evidence-based, the current literature was reviewed and critically appraised. Preliminary statements were drafted based on the review of the relevant literature. During a conference call, the whole group discussed each preliminary statement and a first round of voting was carried out. Statements were removed when a consensus among group members was not obtained. The voters had the opportunity to provide comments/suggestions with their votes. The statements were then revised accordingly. Another round of voting was carried out according to the same rules to allow the whole group to evaluate the revised version of the statements. The group achieved consensus on 18 statements. This Consensus Statement presents these ESGO/ISUOG/IOTA/ESGE statements on the pre-operative diagnosis of ovarian tumors and the assessment of carcinomatosis, together with a summary of the evidence supporting each statement.

INTRODUCTION

The accurate characterization of newly diagnosed adnexal lesions is of paramount importance to define appropriate treatment pathways. Patients with masses that are suspicious for malignancy should be referred to a gynaecological oncology center, in order to receive specialist care, as per the definitions of the European Society of Gynaecological Oncology (ESGO) and national and international recommendations and guidelines. For a non-gynaecological primary tumor, patients need to be referred to an appropriate specialist, while patients with benign lesions may be followed up and treated conservatively or may be suitable for less radical surgical treatment, depending on the clinical context.2–7 Treatment decision-making processes should be based on a combination of the patient’s overall clinical picture, symptoms, preferences, previous medical and surgical history, tumor markers, and clinical and radiological findings. A single diagnostic modality alone should not determine the patient’s journey.

The ESGO, the International Society of Ultrasound in Obstetrics and Gynecology (ISUOG), the International Ovarian Tumour Analysis group (IOTA), and the European Society for Gynaecological Endoscopy (ESGE) have, jointly, developed clinically relevant and evidence-based statements on the pre-operative diagnosis of ovarian tumors and assessment of disease spread, including imaging techniques, biomarkers, and predictive models. Neither screening and follow-up modalities nor economic analysis of the imaging techniques, biomarkers, and prediction models addressed herein are included within the remit of this Consensus Statement.

RESPONSIBILITIES

The present series of statements form a consensus of the authors regarding their currently accepted approaches for the pre-operative diagnosis of ovarian tumors and assessment of disease spread, based on the available literature and evidence. Any clinician applying or consulting these statements is expected to use independent medical judgment in the context of individual clinical circumstances to determine all patients’ care and treatment. These statements are presented without any warranty regarding their content, use or application, and the authors disclaim any responsibility for their application or use in any way.

METHODS

This Consensus Statement on the pre-operative diagnosis of ovarian tumors and assessment of disease spread was developed using an eight-step process, chaired by Professors Christina Fotopoulou and Dirk Timmerman.
Joint statement

Timmerman

Consensus Statement on the pre-operative diagnosis of ovarian tumors and assessment of disease spread.

Nomination of multidisciplinary international group

Identification of scientific evidence

Formulation of preliminary consensus statements

Discussion of each preliminary consensus statement

First round of voting

Revision of consensus statements (where necessary)

Second round of voting

Finalization of statements

Figure 1 Eight-step process for development of the Consensus Statement on the pre-operative diagnosis of ovarian tumors and assessment of disease spread.

RESULTS

General remarks

Even though the test performance of any biochemical or radiological diagnostic test appears to increase after excluding borderline ovarian tumors and non-gynecological primary tumors, such as of the gastrointestinal tract or breast, we included in our literature assessment studies addressing all types of adnexal tumors as this is a better reflection of clinical reality.

Ultrasonography

A transvaginal ultrasound examination is often regarded in clinical practice as the standard first-line imaging investigation for the assessment of adnexal pathology. The diagnostic accuracy of ultrasonography in differentiating between benign and malignant adnexal masses has been shown to relate to the expertise of the operator. The European Federation of Societies for Ultrasound in Medicine and Biology has published minimum training requirements for gynecological ultrasound practice in Europe, including standards for theoretical knowledge and practical skills. These identify three levels of training and expertise. Thus, Level III (expert) can be attributed to a practitioner who is likely to spend the majority of their time undertaking gynecological ultrasound and/or teaching, research and development in the field. A Level II practitioner should have undertaken at least 2000 gynecological ultrasound examinations. The training required to attain this level of practice would usually be gained during a period of expert ultrasound training, which may be within, or after completion of, a specialist training program. To maintain competence at Level II, practitioners should perform at least 500 examinations each year. A Level I practitioner should have performed a minimum of 300 examinations under the supervision of a Level II practitioner or an experienced Level
I practitioner with at least 2 years' regular practical experience. To maintain Level I status, the practitioner should perform at least 300 examinations each year. A prospective randomized controlled trial to assess the effect of the quality of gynecological ultrasonography on the management of patients with suspected ovarian cancer has shown that women with a Level III (expert) ultrasound examination undergo significantly fewer unnecessary major procedures and have a shorter inpatient hospital stay compared with those having a Level II (routine) examination by a sonographer.9

Subjective assessment by expert ultrasound examiners has excellent performance to distinguish between benign and malignant ovarian tumors.9–14 In many cases, expert examiners should be able to narrow the diagnosis down further to a specific histological sub-type. The typical pathognomonic ultrasound features of some key histological types have been published in the series ‘Imaging in gynecological disease’ in Ultrasound in Obstetrics and Gynecology (https://obgyn.onlinelibrary.wiley.com/toJ10.1002/ISSN)1469-0705.IMAGINGINGYNECOLOGICALDISEASE). The most common and typical findings for each pathology are summarized in Table 1.

Risk of malignancy index (RMI) and risk of ovarian malignancy algorithm (ROMA)
Several attempts have been made to develop more objective ultrasound-based approaches for discriminating between benign and malignant adnexal tumors. These include the risk of malignancy index (RMI), a scoring system based on menopausal status, a transvaginal ultrasound score, and serum cancer antigen 125 (CA 125) level.15 Many studies have demonstrated the diagnostic performance of the RMI in classifying adnexal masses.11 17–28 Three variants of the RMI (RMI-II, RMI-III, RMI-IV) have been developed, but these offer no significant additional diagnostic advantage compared with the original version (RMI-I).11 22 27 28 Moore et al50 developed an algorithm, the risk of ovarian malignancy algorithm (ROMA), based on both CA 125 and human epidymis protein 4 (HE4). Westwood et al51 pooled data comparing the ROMA with the RMI-I to guide referral decisions for women with suspected ovarian cancer and found similar performance if women with borderline tumors and non-epithelial cancers were excluded from the analyses. More recently, another meta-analysis showed a higher specificity of the RMI-I than the ROMA in pre-menopausal women but a similar performance for detecting ovarian cancer in post-menopausal women presenting with an adnexal mass.17 Limitations of the RMI are the absence of an estimated risk of malignancy and its considerable dependency on serum CA 125, the latter resulting in a relatively low sensitivity for early-stage invasive and borderline disease, especially in pre-menopausal women31 32 (see Tumor Markers).

IOTA methods
To homogenize and standardize the quality, description, and evaluation of ultrasonography across different centers, and thereby increase diagnostic accuracy, the IOTA group first published a consensus paper on terms and definitions to describe adnexal lesions in 2000.33 Using this standardized methodology, the IOTA group has developed different prediction models based on logistic regression analysis.34–36 In a large-scale external validation study, Van Holsbeke et al52 showed that the IOTA logistic regression models 1 (LR1, with 12 variables) and 2 (LR2, with six variables) outperformed 12 other models, including the RMI. The LR2 model was easier to use than the LR1 model. Demonstrating the standardization and reproducibility of the IOTA models, Sayasneh et al53 showed that even less experienced sonographers are able to differentiate accurately between benign and malignant ovarian masses using the IOTA LR1 model. The IOTA group also developed ‘Simple Rules’ that may be applied to a mass based on the presence or absence of five benign and five malignant ultrasound features. These rules can be applied to about 80% of adnexal masses, with the rest being classed as inconclusive. They have now been broadly accepted and are widely used in clinical practice.38–46 More recently, a logistic regression model based on the ultrasound features of the original Simple Rules was developed—the Simple Rules risk model. This model is able to provide an individual estimated risk of malignancy for any type of lesion.39 A summary of the main models and scoring systems for the pre-operative diagnosis of ovarian tumors is shown in Table 2.

As many ovarian masses can be recognized relatively easily, the IOTA group also proposed four ‘Simple Descriptors’ of the features typical of common benign lesions and two suggestive of malignancy, which can give an ‘instant diagnosis’ and reflect the pattern recognition that is a key part of ultrasonography. These are applicable to about 43% of adnexal masses.47 A three-step strategy, consisting of the sequential use of Simple Descriptors, Simple Rules, and subjective assessment by an expert, had high accuracy for discriminating between benign and malignant adnexal lesions.47 A systematic review and meta-analysis reported better performance of the IOTA Simple Rules and the IOTA LR2 model compared with all other scoring systems, including the RMI.48 Besides confirming these findings, another meta-analysis highlighted that a two-step approach, with the IOTA Simple Rules as the first step and subjective assessment by an expert for inconclusive tumors as the second step, matched the test performance of expert ultrasound examiners.11 The IOTA Simple Rules have been integrated into several national clinical guidelines for the evaluation and management of adnexal masses,49 50 and they were considered the main diagnostic strategy51 as part of a first international consensus report for the assessment of adnexal masses.

A randomized controlled trial assessing surgical intervention rates and the oncologic safety of decision-making processes using an RMI-based protocol developed by the British Royal College of Obstetricians and Gynaecologists (RCOG) versus triage using the IOTA Simple Rules42 showed that the IOTA protocol resulted in lower surgical intervention rates compared with the RMI-based RCOG protocol. The IOTA Simple Rules did not result in more cases in which a diagnosis of cancer was delayed. It was found that the addition of biomarkers such as serum CA 125 and HE4 when using the IOTA Simple Rules, with or without subjective assessment by an expert sonographer, offered no additional diagnostic advantage for the characterization of ovarian masses, but was more costly than a three-step strategy based on the sequential use of the IOTA Simple Descriptors, Simple Rules, and expert evaluation.53 54

The IOTA group have also developed the Assessment of Different NEOplasias in the adnexa (ADNEX) model. This multiclass prediction model is the first risk model to differentiate between benign and malignant tumors, while also offering sub-classification of any malignancy into borderline tumors, Stage I, and Stage II–IV primary

cancers and secondary metastatic tumors. The IOTA ADNEX model was developed and validated using parameters collected by experienced ultrasound examiners. Several external validation studies have shown good to excellent performance of the ADNEX model in discriminating different types of ovarian tumor, with a higher clinical value than the RMI. A study aiming to validate the ADNEX model when applied by Level II examiners has confirmed that it can be used successfully by less-experienced examiners. A large multicenter cohort study of 4905 masses in 17 centers, comparing six different prediction models (RMI, LR2, Simple Rules, Simple Rules risk model, and ADNEX model with or without CA 125), demonstrated the IOTA ADNEX model and the IOTA Simple Rules risk model to be the best models for the characterization of ovarian masses in patients who present with an adnexal lesion.

**Gynecologic Imaging Reporting and Data System (GI-RADS)**

The Gynecologic Imaging Reporting and Data System (GI-RADS) was first introduced by Amor et al in 2009 and was validated prospectively by the same team in a multicenter study 2 years later. This reporting system quantifies the risk of malignancy into five categories: GI-RADS 1, definitively benign (estimated probability of malignancy (EPM) 0%); GI-RADS 2, very probably benign (EPM <1%); GI-RADS 3, probably benign (EPM 1–4%); GI-RADS 4, probably malignant (EPM 5–20%); and GI-RADS 5, very probably malignant (EPM >20%). More recently, several studies have demonstrated the value of the GI-RADS system for the assessment of malignant adnexal masses in women who are candidates for surgical intervention. Furthermore, the addition of GI-RADS to CA 125 improves the identification of adnexal masses at high risk of malignancy compared with using CA 125 alone.

**Ovarian-Adnexal Reporting and Data System (O-RADS)**

The Ovarian-Adnexal Reporting and Data System (O-RADS) lexicon for ultrasound was published in 2018, providing a standardized glossary that includes all appropriate descriptors and definitions of the characteristic ultrasound appearance of normal ovaries and various adnexal lesions. The O-RADS ultrasound working group developed an adnexal mass triage system based either on the O-RADS descriptors or on the risk of malignancy assigned to the mass using the IOTA ADNEX model to classify ovarian tumors into different risk categories. However, at present, neither the triage system nor the O-RADS descriptors have been externally validated. Basha et al determined the malignancy rates, validity, and reliability of the O-RADS approach when applied to a database of 647 adnexal masses collected before the development of the O-RADS system. In this retrospective study, the O-RADS system had significantly higher sensitivity than did the GI-RADS system and the IOTA Simple Rules, with a non-significant slightly lower specificity compared with both GI-RADS and IOTA Simple Rules, and with similar reliability.

**Statements on ultrasonography (Statements 1–6)**

1. Subjective assessment by expert (Level III) ultrasound examiners has the best performance to distinguish between benign and malignant ovarian tumors.
   - Level of evidence: 1a
   - Grade of statement: A
### Table 2  Summary of main models and scoring systems for pre-operative diagnosis of ovarian tumors (modified from reference 63)

</table>
| **Simple descriptors:** classification as benign or malignant | Benign descriptor (BD) 1: unilocular tumor with ground-glass echogenicity in a pre-menopausal woman  
BD2: unilocular tumor with mixed echogenicity and acoustic shadows in a pre-menopausal woman  
BD3: unilocular anechoic tumor with regular walls and maximum diameter of lesion <10 cm  
BD4: remaining unilocular tumor with regular walls  
Malignant descriptor (MD) 1: Tumor with ascites and at least moderate color Doppler blood flow in a post-menopausal woman  
MD2: age >50 years and CA 125 >100 U/mL | No risk estimates  
Based on clinical, ultrasound and CA 125 information  
Possible to calculate result without computer |
| **RM: score** | CA 125, menopausal status, ultrasound score based on five binary ultrasound variables (multilocular cyst, solid areas, bilateral lesions, ascites, evidence of metastases on abdominal ultrasound) | No risk estimates  
Based on clinical, ultrasound and CA 125 information  
Possible to calculate result without computer  
Online calculators available |
| **Simple Rules:** classification as benign, inconclusive or malignant | Classification based on 10 binary features—five benign and five malignant features:  
Benign features: unilocular cyst, smooth multilocular cyst with largest diameter <100 mm, presence of solid areas with largest diameter <7 mm, acoustic shadows, no vascularization on color Doppler  
Malignant features: irregular solid tumor, irregular multilocular solid tumor with largest diameter ≥100 mm, presence of ascites, ≥4 papillary projections, very strong vascularization on color Doppler | No risk estimates  
Classification into only three groups  
Based on dichotomized ultrasound features  
Easy to use without computer  
Available as smartphone app |
| **LR2: risk model based on logistic regression** | Age (years), presence of acoustic shadows, presence of ascites, presence of papillary projections with blood flow, maximum diameter of largest solid component, irregular internal cyst walls | Risk estimates  
Based on clinical and ultrasound information  
Requires computer  
Available as smartphone app |
| **Simple Rules risk model based on logistic regression** | The 10 binary features used in the Simple Rules, type of center (oncology center vs other) | Risk estimates  
Based on dichotomized ultrasound features  
Developed to add risk estimates for Simple Rules  
Available as online calculator; available in ultrasound machines from some manufacturers |
| **ADNEX without CA 125: risk model based on multinomial logistic regression** | Age (years), maximum diameter of lesion (mm), maximum diameter of largest solid component (mm), number of papillary projections (ordinal), presence of acoustic shadows, presence of ascites, presence of more than 10 cyst locules, type of center (oncology center vs other) | Risk estimates  
Also estimates risk of four subtypes of malignancy  
Based on clinical and ultrasound information  
Subjective predictors are avoided a priori (eg, color score or irregular cyst walls)  
Requires computer  
Available as smartphone app and as online calculator; available in ultrasound machines from some manufacturers |

ADNEX, Assessment of Different NEoplasias in the adneXa; CA 125, cancer antigen 125; RMI, risk of malignancy index.

2. If an expert ultrasound examiner is not available, the use of ultrasound-based diagnostic models can assist clinicians to distinguish between benign and malignant ovarian tumors.
   - Level of evidence: 2b
   - Grade of statement: B
   - Consensus: yes, 95% (n=19); no, 0% (n=0); abstain, 5% (n=1)

4. The IOTA ADNEX model and the IOTA Simple Rules risk model are recommended as they outperform existing morphological scoring systems, including the RMI.
   - Level of evidence: 1b
   - Grade of statement: A
   - Consensus: yes, 95% (n=19); no, 0% (n=0); abstain, 5% (n=1)

5. The IOTA ADNEX model is a multiclass model and is helpful to differentiate between benign tumors, borderline tumors, early- or advanced-stage ovarian cancer, and secondary metastatic tumors.
   - Level of evidence: 3b
   - Grade of statement: C
   - Consensus: yes, 85% (n=17); no, 0% (n=0); abstain, 15% (n=3)

6. The threshold risk of there being a secondary metastatic tumor (as predicted by the IOTA ADNEX model), above which additional investigations to detect the primary organ of origin should be triggered, is 10%.
   - Level of evidence: 5
   - Grade of statement: D
   - Consensus: 5% threshold, 10% (n=2); 10% threshold, 75% (n=15); 15% threshold, 0% (n=0); 20% threshold, 0% (n=0); abstain, 15% (n=3)

Levels of evidence and grades are described in Online supplemental appendix 2.

Tumor markers

According to a systematic quantitative review assessing the accuracy of CA 125 level in the diagnosis of benign, borderline, and malignant ovarian tumors, CA 125 is the best available single-protein biomarker identified to date. Although it lacks sensitivity and specificity for early stages of the disease and has a relatively low specificity overall, it can help direct treatment options in patients with suspicious ovarian masses. Pooled analyses have highlighted that a high body mass index and ethnicity might influence CA 125 levels, representing an additional diagnostic challenge. Other factors that influence CA 125 levels are the age of the patient, pregnancy, inflammatory processes, and the presence of fibroids or endometriosis.

Multiple studies, including meta-analyses, have highlighted the role of HE4 as a potential complement to CA 125, especially in differentiating benign endometriotic and inflammatory lesions in younger women. Additional tumor markers (as in the ROMA test) have failed to improve significantly the discrimination between benign and malignant masses compared with CA 125 alone.

The combination of a more extended tumor marker profile, including the addition of carcinoembryonic antigen (CEA) and/or carbohydrate antigen (CA 19-9) to CA 125, is useful mainly for differentiating between metastatic tumors from the gastrointestinal tract or pancreas and primary ovarian malignancy.

Statements on tumor markers (Statements 7–12)

7. CA 125 is the best single-protein biomarker for the pre-operative characterization of ovarian tumors. However, it is not useful as a screening test for ovarian cancer.
   - Level of evidence: 2b
   - Grade of statement: B
   - Consensus: yes, 95% (n=19); no, 0% (n=0); abstain, 5% (n=1)

8. Neither HE4 nor ROMA improves the discrimination between benign and malignant masses compared with CA 125 alone.
   - Level of evidence: 2b
   - Grade of statement: B
   - Consensus: yes, 70% (n=14); no, 0% (n=0); abstain, 30% (n=6)
Joint statement

9. CA 125 does not increase the performance of ultrasound-based risk models to distinguish between benign and malignant tumors.
   - Level of evidence: 2b
   - Grade of statement: B
   - Consensus: yes, 60% (n=12); no, 10% (n=2); abstain, 30% (n=6)

10. CA 125 is helpful as a biomarker in cases of suspected malignancy and it helps to distinguish between sub-types of malignant tumors, such as borderline and early- and advanced-stage primary ovarian cancers and secondary metastatic tumors.
    - Level of evidence: 2b
    - Grade of statement: B
    - Consensus: yes, 90% (n=18); no, 5% (n=1); abstain, 5% (n=1)

11. CEA may be useful in specific cases to differentiate between primary ovarian cancer and secondary (ovarian) tumors.
    - Level of evidence: 3b
    - Grade of statement: C
    - Consensus: yes, 90% (n=18); no, 0% (n=0); abstain, 10% (n=2)

12. CA 19-9 can help to differentiate secondary metastatic tumors in the ovary.
    - Level of evidence: 3b
    - Grade of statement: C
    - Consensus: yes, 75% (n=15); no, 5% (n=1); abstain, 20% (n=4)

Levels of evidence and grades are described in Online supplemental appendix 2.

Magnetic resonance imaging/computed tomography/positron emission tomography-computed tomography

Magnetic resonance imaging
Several reports have found that magnetic resonance imaging (MRI), alone or in combination with computed tomography (CT), predicts accurately the presence of peritoneal carcinomatosis in patients undergoing pre-operative evaluation for cytoreductive surgery, particularly when the assessment is carried out by an experienced radiologist.\(^{114-117}\) Recently, a prospective study reported higher specificity of the IOTA LR2 model compared with subjective interpretation of MRI findings by an experienced radiologist, as well as similar sensitivities for both imaging modalities for discriminating between benign and malignant tumors.\(^{118}\) The addition of diffusion-weighted techniques to conventional imaging modalities has been shown in multiple pooled studies to increase diagnostic accuracy in discriminating between benign tumors and ovarian cancer, especially in the Caucasian population, with data even suggesting a value in predicting resectability.\(^{119-123}\) However, the true extent of such a benefit needs to be validated further in multicenter large-scale prospective randomized studies, which are currently being designed or underway.\(^{121}\) The addition of...

Investigation of other primary tumor origin

Figure 3  Flowchart of steps necessary to differentiate between subgroups of malignancy and extent of disease within gynecological oncology centers. *Early stage and advanced stage might differ according to different ADNEX models (stage I vs stages III–IV) and oncologically (stages I–II vs stages I–IV). 

quantitative dynamic contrast-enhanced MRI to diffusion-weighted imaging and anatomical MRI sequences and the development of a 5-point scoring system (O-RADS MRI score) is another modern diagnostic development with promising potential for the differentiation between benign and malignant adnexal masses in cases in which ultrasound is unable to arrive at a clear diagnosis (ie, indeterminate masses). When this technique is enhanced with volume quantification, it can help to discriminate between type I and type II epithelial ovarian cancers. However, there are only limited data available on the impact of these modern MRI techniques on clinical decision-making, and further studies are needed with larger sample populations.

Computed tomography

Dedicated multidetector CT protocols with standardized peritoneal carcinomatosis index forms are the most common diagnostic tool used in routine clinical practice to assess the extent of tumor dissemination and the presence of peritoneal carcinomatosis. A radiological peritoneal carcinomatosis index applied at pre-operative CT within an expert setting has been shown to have low performance scores as a triage test to identify patients who are likely to have complete cytoreduction to no macroscopic residual disease. On retrospective analysis, pre-operative CT imaging showed high specificity but rather low sensitivity in detecting tumor involvement at key sites in ovarian cancer surgery. Multiple studies that have attempted to cross-validate the accuracy of CT scans in predicting unresectable disease and incomplete cytoreduction have shown a substantial drop in accuracy rates when attempts have been made to validate them in other cohorts. Thus, CT should not be used as the sole tool to predict the resectability of peritoneal carcinomatosis and exclude patients from surgery; rather, the full clinical context should be taken into account. Its widespread availability makes CT useful as a first-line diagnostic tool to identify patients who should not be selected for cytoreductive surgery, such as those with large/multifocal intra-parenchymatous distant metastases, acute thromboembolic events, or secondary metastatic tumors that limit the prognosis. The role of radiomics as an additional quantitative mathematical segmentation of conventional pre-operative CT images has shown some promising results in preliminary studies; however, larger studies are necessary for validation before this technique is implemented in clinical practice.

Positron emission tomography-computed tomography

Positron emission tomography-computed tomography (PET-CT) may be useful in differentiating malignant from borderline or benign ovarian tumors, with the limitation that its diagnostic performance can be impacted negatively by certain tumor histological sub-types due to the lower fluorodeoxyglucose uptake in clear cell and mucinous invasive subtypes. PET-CT can also play a role as an additional technique in the diagnosis of
lymph node metastases, especially outside the abdominal cavity, or in characterizing unclear lesions in key areas that would alter clinical management (eg, chest lesions). However, PET-CT does not seem to be a relevant additional diagnostic modality for the true extent of peritoneal spread of ovarian cancer, specifically bowel and mesenteric serosa, and therefore fails to predict resectability in those key sites, especially in the presence of low-volume disease. Furthermore, PET-CT has been shown to have a low diagnostic value in differentiating borderline from benign tumors and should therefore not be used in clinical decision-making processes in that context, especially when considering fertility-sparing procedures.

Statements on MRI, CT, and PET/CT (Statements 13–17)

13. MRI with the inclusion of the functional sequences, dynamic contrast-enhanced and diffusion-weighted MRI, is not a first-line tool but may be used as a second-line tool after ultrasonography to further differentiate between benign, malignant, and borderline masses.
   - Level of evidence: 2a
   - Grade of statement: B
   - Consensus: yes, 100% (n=20); no, 0% (n=0); abstain, 0% (n=0)

14. PET-CT and whole-body diffusion MRI as a second step can help to detect non-ovarian origin of secondary metastatic tumors if suspicions are raised by the initial ultrasound examination.
   - Level of evidence: 4
   - Grade of statement: C
   - Consensus: yes, 90% (n=18); no, 0% (n=0); abstain, 10% (n=2)

15. PET-CT cannot differentiate reliably between borderline and benign tumors.
   - Level of evidence: 4
   - Grade of statement: C
   - Consensus: yes, 95% (n=19); no, 0% (n=0); abstain, 5% (n=1)

16. Imaging alone cannot detect reliably the entire extent of either peritoneal carcinomatosis (especially in cases of small-volume carcinomatosis) or mesenteric and bowel serosal involvement.
   - Level of evidence: 3b
   - Grade of statement: B
   - Consensus: yes, 85% (n=17); no, 5% (n=1); abstain, 10% (n=2)

17. Imaging alone should not be used for surgical decision-making in terms of the prediction of peritoneal tumor resectability.
   - Level of evidence: 3b
   - Grade of statement: B
   - Consensus: yes, 80% (n=16); no, 15% (n=3); abstain, 5% (n=1)

Levels of evidence and grades are described in Online supplemental appendix 2.

Circulating cell-free DNA and circulating tumor cells

Circulating cell-free DNA and circulating tumor cells as non-invasive cancer biomarkers and in non-invasive biopsy (sometimes called ‘liquid biopsy’) have been investigated in multiple studies. DNA methylation patterns in cell-free DNA show potential to detect a proportion of ovarian cancers up to 2 years in advance of diagnosis. They may potentially guide personalized treatment, even though validation studies are lacking. The prospective use of novel collection vials, which stabilize blood cells and reduce background DNA contamination in serum/plasma samples, will facilitate the clinical implementation of liquid biopsy analyses. A prospective evaluation of the potential of cell-free DNA for the diagnosis of primary ovarian cancer using chromosomal instability as a read-out suggested that this might be a promising method to increase the specificity of the pre-surgical prediction of malignancy in patients with adnexal masses. However, even though these circulating biomarkers play a key role in understanding metastasis and tumorigenesis and provide comprehensive insight into tumor evolution and dynamics during treatment and disease progression, they still have not been established as part of routine clinical practice.

One meta-analysis suggested that quantitative analysis of cell-free DNA has unsatisfactory sensitivity but acceptable specificity for the diagnosis of ovarian cancer. In a more recent meta-analysis, cell-free DNA appeared to be slightly better than CA 125 and similar to HE4 with respect to its diagnostic ability to discriminate individuals with from those without ovarian cancer. Nevertheless, the diagnostic value of cell-free DNA in patients with ovarian cancer remains unclear and the data should be interpreted with caution. Further large-scale prospective studies are strongly recommended to validate the potential applicability of using circulating cell-free DNA, alone or in combination with conventional markers, as a diagnostic biomarker for ovarian cancer, and to explore potential factors that may influence the accuracy of ovarian cancer diagnosis.

Statement on circulating cell-free DNA and tumor cells (Statement 18)

18. Circulating cell-free DNA and circulating tumor cells should not yet be used in routine clinical practice to differentiate between benign and malignant ovarian masses.
   - Level of evidence: 4
   - Grade of statement: C
   - Consensus: yes, 85% (n=17); no, 5% (n=1); abstain, 10% (n=2)

Levels of evidence and grades are described in Online supplemental appendix 2.

OVERVIEW OF CONSENSUS

The experts also reached a consensus on a flowchart describing steps recommended to distinguish between benign and malignant tumors and to direct patients towards appropriate treatment pathways. Ultrasonography is recommended as a first step to stratify patients with symptoms suggestive of an adnexal mass, and in those with an incidental finding of an adnexal mass on imaging. If the scan rules out normal ovaries and physiological changes (ie, rules out O-RADS 1), the IOTA ADNEX model could be applied as a next step in order to determine the risk of malignancy. Any ultrasonographic examination in the case of a suspected ovarian mass should be performed by an expert sonographer. The resulting classification of the lesion into one of the O-RADS categories can
further guide the management and selection of patients for referral to a dedicated gynecological oncology center.

A consensus was also reached on further steps necessary to differentiate between sub-groups of malignancy and extent of disease within gynecological oncology centers (Figure 3). Ultrasound sound assessment by an expert or application of the IOTA ADNEX model in combination with the tumor marker profile (CA 125 and CEA, complemented with other markers in specific cases) can often indicate the specific sub-type of malignancy. If available, diagnosis of the primary lesion can be confirmed with diffusion- and perfusion-weighted MRI, especially in cases in which fertility-sparing surgery is considered. A CT scan of chest, abdomen, and pelvis is mandatory before planned surgery for presumed malignancy, in order to exclude secondary cancers, thromboembolic events, and multifocal intraperitoneal distant metastases that would preclude resectability. The final management and treatment journey of the patient should be determined within an expert multidisciplinary setting, taking into account both the diagnostic findings and the overall patient profile, including symptoms, patient preferences and prior surgical, medical and reproductive history, with the ultimate aim of defining an individualized approach for every patient.
