Introduction/Background Past management of cervical intra-epithelial neoplasia-2 (CIN-2) has centred around treatment via excision. Contemporaneously, more onus has been placed on conservative management of this disease in women of reproductive age. This is namely to prevent future preterm birth.

Methodology A retrospective analysis was completed of patients undergoing conservative management of biopsy confirmed CIN-2 between 2017–2021 in a single tertiary centre. This included 6 monthly colposcopic assessment for a total 24 months with either smear or biopsy alternatively. Excision was offered in the event of progression or patient choice. Primary outcome was divided into successful regression and discharge back to routine monitoring, progression or persistence requiring intervention, and patient adherence (drop-out or loss to follow-up). Further secondary measures were also examined, including pregnancy outcomes, and a sub-group analysis of smokers and those aged over 35 years old. Statistical analysis was completed using R Studio Ver 1.2.5033.

Results A total of 100 patients underwent conservative management. Primary outcomes are summarised in figure 1. A total of 18 women were treated with LLETZ, including 6 for patient choice. No women had progression of disease to malignancy, and 5 progressed to CIN-3. The average time to dropout was 12.42 months (1–22). Smokers and those over 35 were not significantly more likely to require intervention then the rest of the population (P=1.0000 and p=0.5936 respectively). 15 women became pregnant either during or after management. A total of 12 live births occurred, and 3 losses between 6–12 weeks gestation. A single preterm delivery occurred due to other reasons.

Conclusion • Conservative management represents a safe management to those of reproductive age.
• Therefore, critical reductions in preterm birth and pregnancy loss are possible.

Abstract 2022-RA-1095-ESGO Figure 1
Introduction/Background Radical vaginal trachelectomy (RVT) is one treatment option for early stage cervical carcinoma in young patients wishing to preserve fertility. However, indication for second step hysterectomy following childbearing is not clear. We compared data of patients treated with RVT at Jena University Hospital with current literature.

Results Out of 47 patients, 30 patients had a follow up (FU) of >12 months and 15 patients >48 months (median, 52, range, 12–120). Median age: 31 years (range, 23–41). Tumor stage: 11% pT1a1, 17% pT1a2, 67% pT1b1, 6% pT1b2. Three patients had N1 in final pathologic appraisal and 14 had LVS1 or V1 or perineural infiltration. Histology: 19% adenocarcinoma, 79% squamous cell carcinoma. Pregnancy rate: 27% (75% live births, two pre-term births, one early miscarriage, one termination of pregnancy). Completion hysterectomy was performed in 11% (5/47) after a median of 58 months (range, 12–134) with no evidence of disease. Out of 30 patients, recurrence occurred in one patient (3.3%) on left ovary after 26 months. Tumor characteristics of this patient at diagnosis: pT1b1, squamous, N0, LVS1. She underwent LRH type Q/M C1, but died 5 years after diagnosis because of disease progression. Outcome in our cohort was comparable to data from a review of Smith S. et al., 2020, analyzing 47 articles with 2566 patients: Median follow-up 48 months (range 2–202), median recurrence rate 3.3% (range 0–25%), median time to recurrence 26 months (range 8–44). Pregnancy rate was 23.9%, with a live-birth rate of 75.1%.

Conclusion RVT is an oncologically safe procedure for early cervical cancer with a median recurrence rate of 3.3%. Completion hysterectomy beyond 44 months of uneventful FU appears omittable.

Introduction/Background Recently, we demonstrated that preoperative conization might reduce the disease recurrence in early cervical cancer patients who undergo primary radical hysterectomy (RH) by a minimally invasive surgical (MIS) approach. However, conization is not mandatory as per the current clinical practice guidelines. This, study aimed to compare survival outcomes between MIS and open RH among patients who did not receive preoperative conization.

Methodology From cervical cancer cohorts of two institutions, we identified pathologically node-negative, margin-negative, parametria-negative, 2018 FIGO stage IB1-IB2 cervical cancer patients who received primary Type C RH between July 2006 and June 2020. Patients who received cervical conization before RH were excluded. The study population was divided into MIS (n=196) and open (n=156) groups. Patients’ clinicopathologic characteristics and survival outcomes were compared between the two groups.

Results Between the MIS and open groups, no differences were observed in histologic type, cervical tumor size, and depth of invasion. After a median follow-up of 63.5 months, overall survival was similar between two groups; however, MIS group showed worse disease-free survival (DFS; 5-year rate, 79.4% vs. 91.1%; P=0.011). In multivariate analysis, MIS was identified as an independent poor prognostic factor for DFS (adjusted HR, 2.027; 95% CI, 1.1130–3.635; P=0.018). However, among IB1 patients (n=107), no difference in DFS was observed between the MIS and open groups: multivariate analysis revealed that MIS did not influence the disease recurrence rate (P=0.142).

Conclusion In conization-skipped, 2018 FIGO stage IB1 cervical cancer, MIS might not increase the disease recurrence rate after RH. Accurate preoperative identification of nodal and parametrial involvement is essential for early cervical cancer patients in deciding the surgical approach of RH.
